Position statement of the American Academy of Oral and Maxillofacial Radiology on selection criteria for the use of radiology in dental implantology with emphasis on cone beam computed tomography

Donald A. Tyndall, DDS, MSPH, PhD, a Jeffery B. Price, DDS, MS, b Sotirios Tetradis, DDS, PhD, c Scott D. Ganz, DMD, d Charles Hildebolt, DDS, PhD, e and William C. Scarfe, BDS, MS f

A Position Paper Subcommittee of the American Academy of Oral and Maxillofacial Radiology (AAOMR) reviewed the literature since the original position statement on selection criteria for radiology in dental implantology, published in 2000. All current planar modalities, including intraoral, panoramic, and cephalometric, as well as cone beam computed tomography (CBCT) are discussed, along with radiation dosimetry and anatomy considerations. We provide research-based, consensus-derived clinical guidance for practitioners on the appropriate use of specific imaging modalities in dental implant treatment planning. Specifically, the AAOMR recommends that cross-sectional imaging be used for the assessment of all dental implant sites and that CBCT is the imaging method of choice for gaining this information. This document will be periodically revised to reflect new evidence. (Oral Surg Oral Med Oral Pathol Oral Radiol 2012;113: 817-826)

In 2000, the American Academy of Oral and Maxillofacial Radiology (AAOMR) published a position paper on the role of imaging in dental-implant treatment planning.1 They state, “After reviewing the current literature, the AAOMR recommends that some form of cross-sectional imaging be used for implant cases and that conventional cross-sectional tomography be the method of choice for gaining this information for most patients receiving implants.” Since then, the introduction and increased use of maxillofacial cone beam computed tomography (CBCT) has had an impact on the availability of digital, cross-sectional imaging and expanded imaging clinical applications for dental-implant imaging.2-18

In 2008, the Executive Council (EC) of the AAOMR published an executive opinion statement on the performance and interpretation of CBCT in dentistry.19 The EC proposed guidelines and principles for CBCT use in contemporary dental practice; these included practitioner responsibilities, the requirement for documentation, and the need for radiation-dose and quality-assurance optimization. If CBCT is used (as with any radiographic imaging technology), the benefits to the patient must outweigh the risks associated with exposure to ionizing radiation.

The purpose of developing imaging selection criteria for implant therapy is to identify the most appropriate imaging technology for each stage of patient care.1 The development of selection criteria is based on review of treatment-decision and outcome-assessment studies. Although more than 10 years have passed since publication of the AAOMR position paper on dental implants,1 studies of the clinical efficacy of cross-sectional imaging for implant planning decisions have been equivocal.20-25

The purpose of this document is to summarize current knowledge about maxillofacial imaging (with emphasis on CBCT) for dental, endosseous-implant therapy and to provide up-to-date radiographic selection criteria for dental implantology. The recommendations presented are not prescriptive but rather advisory and are intended to provide the dental profession with current considers opinions on the appropriate imaging for implant dentistry. The underlining goal is to maximize diagnostic efficiency while minimizing patient radiation risk.

CLINICAL CONSIDERATIONS IN SELECTION CRITERIA FOR DENTAL IMPLANTOLOGY

The diagnostic phase of dental-implant therapy and, in particular, the appropriate choice of radiographic ex-
Anatomic considerations

Each location in the dental alveolus has unique morphologic characteristics owing to edentulousness and specific regional anatomic features that need to be identified and assessed in the diagnostic and treatment-planning phase of dental-implant therapy.

The maxillary anterior region (commonly referred to as the esthetic zone) often presents both surgical and prosthetic implant-assessment complexities. Subsequent to tooth loss, decrease in the height and/or width of the alveolar process and the development of a labial concavity often necessitate bone augmentation. The morphology and dimension of the nasopalatine (incisive canal) and the location of the floor of the nasal fossae may also compromise the available bone volume.

The available residual alveolar ridge in the posterior, maxillary molar region is limited superiorly by the floor of the maxillary sinus. Assessment of the extent of this structure, including the locations of septae, is important in determining the bone volume available for implant placement and the possible need for bone-supplementation procedures, such as sinus lift and bone augmentation.

Of the various regions of the maxilla and mandible, the maxillary posterior region has the lowest bone density and the highest implant failure rate. Assessment of the anterior recess of the maxillary sinus is also important if markedly angled implants are considered for implant-supported edentulous prostheses.

Although the anterior mandible is a relatively safe location for implant placement, to avoid intraoperative and postoperative hemorrhage, neurosensory loss, and to increase the likelihood of osseointegration, the locations of osseous and intraosseous neurovascular structures must be identified before osteotomy and subsequent implant placement. Osseous structures include the lingual cortical plates, and neurovascular structures include the lingual foramen, the terminal branch of the inferior alveolar canal, the mandibular incisive canal, the anterior loop, and the mental foramen of the inferior alveolar canal.

In the posterior mandible, there are several anatomic structures that can compromise prosthetically driven, dental-implant placement. The lingual concavity (sub-mandibular gland fossa, submandibular fossa) below the mylohyoid ridge and the inferior alveolar (mandibular) canal have variations that can restrict implant placement. The deficiencies of 2-dimensional imaging techniques for accurate location of the inferior alveolar canal are well documented.

Imaging strategies

A number of radiographic examinations are used for preoperative, dental-implant-site assessment. Clinicians commonly use 2 or more examinations. Each examination has specific indications, advantages, and disadvantages. A perfect imaging examination for dental-implant treatment planning does not exist.

Plain film radiography. This term refers to projection images obtained with a stationary x-ray source and area detector. Plain-film images represent the entire volume through which the x-ray beam is transmitted and is subject to differential magnification, geometrical distortion, and anatomic superimposition.

Intraoral radiography

Periapical intraoral radiography provides images of limited dentoalveolar regions. These images have excellent spatial and contrast resolution with minimal distortions. Images taken using film-holding devices allow regional visualizations of vertical and anteroposterior bounds of residual alveolar ridges and identifica-
tions of adjacent anatomical structures. The technique is the most widely available, inexpensive, and most common initial dental radiographic examination for implant-site assessment. The technique, however, is highly operator dependent and requires a moderate level of patient compliance to provide images with minimal geometrical distortions. Because reproducible imaging geometry is difficult to obtain in areas of extended edentulousness, images of these areas have relatively low reliabilities and accuracies. Vertical accuracy can be improved by using a radiographic marker of known dimension to calibrate image measurements. The greatest limitation of this strategy is the lack of cross-sectional information to access bone volume.

Because occlusal radiography provides information on the general shape of the residual dental arch and maximum bucco-lingual dimension of the alveolar ridge, occlusal radiography has been proposed as a supplement to periapical radiography for implant assessments. Occlusal radiography, however, provides no information in addition to that provided by dental study models, and its use is, therefore, not justified for implant-site assessments.

**Cephalometric radiography**

The entire maxillofacial area is contained within a lateral cephalometric radiograph, which includes 2-dimensional representations of the anteroposterior and vertical relationships of the maxillary and mandibular dental arches. Because of fixed, image-projection geometry, midline structures have constant magnifications, and this allows assessments of interarch, dentoalveolar positions and angulations. Edentulous spaces in the midline are represented as cross-sectional images that can be calibrated to provide accurate measurement of bucco-lingual as well as vertical bone dimensions of the anterior residual alveolar ridge. Equipment for lateral cephalometric radiography is readily available, and cephalometric images are relatively easy to obtain and of low cost. The use of these images is limited, however, in that they provide uniformly magnified images of midline structures only. Although oblique, lateral cephalograms are used to image anterolateral segments, the alveolar process is often obscured by the superimposition of teeth adjacent to the edentulous alveolus.

**Rotational panoramic radiography.** This is the most commonly used extraoral imaging modality in implant dentistry. With rotational panoramic radiography, the jaws are placed within a focal trough (a volumetric curved columnar space), and a narrow x-ray beam moves in synchrony and in opposite directions with an x-ray receptor. The result is a projection image of the jaws. Panoramic radiographs provide information on the inferior alveolar canals and maxillary sinus and may show pathologic conditions not demonstrated on complete, intraoral radiographic examinations. Panoramic radiography is commonly available, is relatively low cost, provides information on both dental arches, and is useful in the initial diagnostic phase of implant planning. By calculating the ratio between image dimensions and known dimensions of radiopaque markers on a radiographic stent, estimates of the vertical distances between the alveolar crest and anatomic structures can be estimated at specific positions in a panoramic image. Many factors, however, limit the accuracy and reliability of this calculation. These include (1) patient-positioning errors, (2) inherent distortions related to equipment differences, (3) discrepancies between the shape of the dental arch and focal trough, and (4) beam angulation. Only 17% of measurements from the crest of the residual alveolar ridge to the inferior alveolar canal have errors of ±1 mm. A major limitation of panoramic radiography is that bucco-lingual assessments cannot be made. Because of its inherent limitations, panoramic radiography is considered unsuitable as a single imaging source for dental-implant site assessment.

**Cross-sectional imaging techniques.** Cross-sectional imaging techniques produce in-focus, thin-section images. Cross-sectional images can be produced with conventional tomography, panoramic-based scanography and tomography, CBCT, and computed tomography (CT). (In this position paper, the term “computed tomography” and the abbreviation “CT” represent scanners that use multirow, detector arrays. CT scanners are most commonly used in medical radiology departments and hospitals.) Tomographic images can also be obtained with magnetic resonance (MR) imaging. Tomographic techniques produce multiple, contiguous image sections (slices) with minimal distortions, and uniform thicknesses and magnifications. In addition, images can be reconstructed such that they are perpendicular to each other. The main advantage of these images for implant dentistry is that they minimize or eliminate anatomic superimposition. Image sections perpendicular to the long axis of the region (object) of interest (e.g., the mandibular arch) are referred to as cross-sectional trans-axial images. Cross-sectional images provide optimal accuracy for visualizing the bony architecture of the jaws.

**Conventional tomography**

Unimodal machines capable of conventional tomography for the assessment of implant sites gained increasing popularity throughout the 1980s and 1990s. In conventional tomography, the x-ray
source and the receptor move in synchrony and in opposite directions to each other about a fixed fulcrum, and this results in the blurring of structures outside the image plane, which is at the level of the fulcrum. For implant dentistry, this provides uniformly magnified images in 2 dimensions usually sagittal and coronal (cross-sectional). A limitation of this technique is that it produces images of limited regions (a few teeth) of a single dental arch. Only objects within the specific region of interest are in focus. Usually stents with radiopaque markers are needed to confirm positions of imaged sites. Because of blurring outside the region in focus, it is often difficult to identify structures and interpret the images.64-66 Increasing complex, synchronized, poly-directional movement patterns (e.g., circular, elliptic, hypocycloidal and tri-spiral) increase image clarity but also increase patient dose. These limitations reduce the usefulness of this technique for implant dentistry, particularly for the assessment of multiple jaw regions.

Panoramic-based tomography
Some panoramic units use x-ray beam motions and area receptors to produce planar or curved (scanogram) tomographic images. Units vary markedly in the anatomic localization methods used, the number and thickness of tomographic slices, and the resultant image magnifications. Images are often extremely wide compared with the area under study, may not cover the region of interest sufficiently, and suffer from blur, making interpretation of images difficult.67 Although this technique can be helpful in preliminary evaluations of specific implant sites, the technique is time-consuming and multiple inter- or intra-arch implant site assessments require multiple exposures.

Computed tomography
Data acquisition in CT has evolved over the past 4 decades with 4 generations of CT scanners. The most advanced systems use fan-beam radiation and multiple detector arrays. Usually, one source of fan-beam radiation is used. The user makes selections to define the spatial resolution, field of view (FOV), and image sharpness. As the object being scanned is translated through the CT scanner, the object attenuates the x-ray beam, and the attenuated x-ray beam data are collected by detector arrays. From the volume of data that is collected, mathematical formulas are used to reconstruct volumetric and/or multiplanar images. The multiplanar reconstructions can have various image thicknesses (several mm to tenths of mm) and be in any image plane (sagittal, coronal, axial, or any plane in between). Images are undistorted, calibrated for dimensional accuracy, and have high soft tissue and hard tissue contrast resolution.68 With the use of phantoms and appropriate calibrations, small changes in radiodensities can be detected.69 Dual-source, dual-energy CT has been developed for use in angiography and for making more accurate measurements of hard and soft tissues. New techniques are being introduced for exposure reductions with the use of CT. CT is relatively expensive and usually available in hospitals and medical imaging centers only.

Cone beam computed tomography
CBCT differs from CT in that it uses a single x-ray source that produces a cone beam of radiation (rather than a fan beam, as with CT). There is no accepted definition of when a fan beam (which is assumed to be planar) becomes a cone beam.70 CBCT uses a single, relatively inexpensive, flat-panel or image intensifier radiation detector. CBCT imaging is performed using a rotating platform to which the x-ray source and detector are fixed. The x-ray source and detector rotate around the object being scanned and multiple, sequential, planar projection images are acquired in an arc of 180° or greater and are mathematically reconstructed into a volumetric dataset.71 Only one rotational sequence is necessary to acquire enough data for volumetric image construction because the entire FOV is irradiated simultaneously. The first CBCT unit with specific maxillofacial application (the NewTom DVT 9000; QR srl, Verona, Italy) became commercially available in Europe in 1999. The adoption of this technology in dentistry has expanded exponentially since then owing to numerous technical improvements and commercial market forces. Many CBCT devices are now multimodal, providing panoramic and cephalometric imaging. Most have a low footprint suitable for dental office placement, are technically as easy to operate as panoramic units, allow collimation of the beam to the region of interest to reduce patient radiation exposures, and produce submillimeter resolution images of high quality. Although CBCT images have high spatial resolution, the data from which images are created contains considerable noise caused by scattered radiation. Because formulas do not exist to correct for this scattered radiation, soft tissue contrast in CBCT images is inferior to that in CT images and CBCT images are not appropriate for detecting small changes in radiodensities.

Both CT and CBCT volumetric datasets can be exported in DICOM (Digital Imaging and Communications in Medicine) format and imported into third-party software that is specifically designed for implant planning. With such software, various 3-dimensional and cross-sectional images can be created. It is also possible to
create virtual image-displays; simulated, implant placements\(^2,15,72\); and to use the software for computer-guided surgery.\(^6,8-10,60-62,72\) Both CT and CBCT are used to perform multidimensional, presurgical assessments of anatomy, thereby reducing the possibilities of incorrect implant placements, which can result in untoward sequelae, such as perforations of cortical borders and invasions of adjacent structures.\(^7\) In comparison with conventional dental imaging, volumetric, data sets provide additional information that can be used for more sophisticated analyses and expanded, treatment-planning options that result in higher likelihoods for achieving satisfactory prosthetic results. For use in implant dentistry, a major advantage of CBCT compared with CT is that CBCT equipment is usually far less expensive than CT equipment. Another advantage is that CBCT software for use in planning implants is usually much easier to use and far more useful than is software available with CT. The primary disadvantages of both CT and CBCT are their relative higher effective radiation exposures\(^7\) and additional costs compared with plain, panoramic and some other cross-sectional radiographic methods.

**Magnetic resonance imaging**

With MR imaging (which does not use ionizing radiation), cross-sectional images (suitable for dental-implant treatment planning) can be created\(^78-82\) The limitations of these images for dental-implant imaging are the increased imaging scan times, dentists’ unfamiliarity with MR images, and higher costs. For dental-implant imaging, MR images are of research and educational interest only.

**RADIATION DOSE CONSIDERATIONS**

Understanding the radiation dose imparted to the patient is an important patient safety issue. Appropriate selection criteria must be used with the minimum radiation exposures that result in images of acceptable diagnostic qualities.\(^19,81\) This concept is known as ALARA (as low as reasonably achievable). Radiation effective doses are available \((E_{2000})\)\(^82\) for various maxillofacial imaging modalities, including CT and CBCT.\(^3,7,77,83-90\) Although CBCT usually results in lower doses than CT, both result in substantially higher doses to patients than do other dental-implant imaging methods. With both CT and CBCT, there is wide variability in doses among different systems and among different imaging protocols (slice thickness, FOV, mAs, kVp, scan time). It is recommended that appropriate selection criteria be used along with imaging protocols that use the minimal doses that ensure acceptable diagnostic qualities.

**PRINCIPLES OF IMAGING FOR DENTAL-IMPLANT ASSESSMENT**

The basic principles of radiology apply to imaging for implant evaluations. Images should have appropriate diagnostic quality and not contain artifacts that compromise anatomic-structure assessments. Images should extend beyond the immediate area of interest to include areas that could be affected by implant placements. Practitioners should have appropriate training in operating radiographic equipment and competence in interpreting images from the modality used. This training and competence should be maintained through continuing dental education courses. Such training should include a thorough review of normal maxillofacial anatomy, common anatomic variants, and imaging signs of diseases and abnormalities. This is particularly important for CT and CBCT\(^7\) imaging because of the complexity of structures within the expanded FOVs.

The goal of radiographic selection criteria is to identify appropriate imaging modalities that complement the goals at each stage of implant therapy. The use of specific imaging is based on professional judgment (i.e., the clinician’s professional opinion as to whether or not information from the clinical examination is inadequate and imaging is needed to formulate a diagnosis and a treatment plan, and/or for use at surgery). Professional judgment varies depending on the skill, competence, knowledge, and experience of the clinician. Specific considerations must include clinical and anatomic complexity, potential risks of complications, and esthetic outcomes. The following selection criteria recommendations provide literature-based, consensus-derived, clinical guidance for practitioners on the appropriate imaging (with particular relevance to CBCT) at each phase of dental-implant therapy.

1. **Initial examination**

Maxillofacial imaging interfaces with patient history, clinical examination, definitive diagnosis, treatment planning, and implant therapy. The purpose of the initial radiographic examination is to assess the overall status of the remaining dentition, to identify and characterize the location and nature of the edentulous regions, and to detect regional anatomic abnormalities and pathologies. Any of these may have important ramifications in the overall timing and sequencing of treatment phases, such as implant loading protocols and postprosthetic occlusal protection.

**Recommendation 1.** Panoramic radiography should be used as the imaging modality of choice in the initial evaluation of the dental implant patient.

**Recommendation 2.** Use intraoral periapical radiography to supplement the preliminary information from panoramic radiography.
Recommendation 3. Do not use cross-sectional imaging, including CBCT, as an initial diagnostic imaging examination.

2. Preoperative site specific imaging
Imaging for presurgical, dental-implant planning must provide information supportive of the following goals.
1. Establish the morphologic characteristics of the residual alveolar ridge (RAR). The morphology of the RAR includes considerations of bone volume and quality. Vertical bone height, horizontal width, and edentulous saddle length determine the amount of bone volume available for implant fixture placement. This information is necessary to match the available bone dimensions with the number and physical dimensions of the implant(s). Moderate deficiencies in horizontal and vertical bone may be corrected by augmentation procedures at the time of the osteotomies and fixture placements, whereas severe deficiencies require prior surgical procedures, such as ridge augmentations. Similarly excessive or irregular vertical alveolar bone may require preprosthetic or simultaneous alveolooplasty.

It is generally agreed that the success of dental-implant placement depends on oral bone quality. Currently, however, there is no agreed on definition for the term “bone quality” and no agreed on method for assessing bone quality. Bone quality is considered good when there is enough cortical and trabecular (cancellous) bone to hold the implant securely (which is required for osseointegration) and is considered poor when there is inadequate oral bone to hold the implant securely. Based on the abundance of published articles on assessments of osteoporosis risks, there is little doubt that oral-radiographic procedures are useful in assessing bone quality; however, few studies have been devoted to assessing oral-bone quality for implant placements. The most commonly used classification system for assessing oral-bone quality for implant placement was introduced in 1985 and uses 4 radiographic oral-bone classes that are based on visual assessments of the amounts of the cortical and trabecular bone.91 The use of dental-radiographic trabecular features for the assessment of implant sites has received little research attention other than visual assessments of dense and sparse trabeculation on radiographic images.92 Although several radiographic methods for assessing alveolar-bone quality have been suggested, no method has been tested in large clinical trials and no method can be recommended at this time. Better assessments of bone quality may influence surgical technique, implant selection (i.e., length, diameter, and type) and the loading protocol. Research in this area is needed.

2. Determine the orientation of the RAR. The orientation and residual topography of the alveolar-basal bone complex must be assessed to determine whether or not there are variations that could compromise the alignment of the implant fixture with the planned prosthetic restoration. This is particularly important in the mandible (e.g., submandibular gland fossa) and anterior maxilla (e.g., labial cortical bone concavity).

3. Identify local anatomic or pathologic conditions restricting implant placement. There are many internal anatomic features that are not easily identified or localized by clinical examination or conventional radiographic imaging that can compromise and limit implant fixture placement or risk involvement of adjacent structures. In the maxilla, these include the incisor region (nasal fossa and canal, nasal fossa), the canine region (canine fossa, nasal fossa), and the premolar/molar region (floor of the maxillary sinus). In the mandible, these include the incisor region (lingual foramen), canine/premolar region (mental foramen), and molar region (submandibular gland fossa, inferior alveolar [mandibular] canal containing the neurovascular bundle).

4. Match imaging findings to the prosthetic plan. Successful implant treatment planning involves both surgical and prosthetic considerations. Radiographic images are not only used for prosthetic planning, but are also used to construct templates to guide surgical procedures and implant placements. The use of guided surgery for implant placement is increasing because of a number of clinical advantages, including increased practitioner confidence and reduced operating time. Guided surgery requires imaging capable of providing DICOM data (either CT or CBCT). These data are imported into software programs where interactive surgical and prosthetic tools can provide complex implant “simulations” within a virtual patient.

Most studies indicate that data from panoramic and intraoral radiography alone are inadequate to accomplish these goals (particularly no. 4) and provide insufficient information to determine treatment difficulty.

Recommendation 4. The radiographic examination of any potential implant site should include cross-sectional imaging orthogonal to the site of interest. This reaffirms the previously stated position of the AAOMR.1

Conventional tomography provides cross-sectional information but is technique sensitive and the images are more difficult to interpret than CBCT. CBCT usually results in lower patient exposures to ionizing radiation than does CT.
**Recommendation 5.** CBCT should be considered as the imaging modality of choice for preoperative cross-sectional imaging of potential implant sites.

As with any type of imaging, a patient should be exposed to the least amount of ionizing radiation that is needed to produce CBCT images of acceptable diagnostic quality. This is achieved by careful selection of exposure parameters and FOV. Although the FOV should be limited to the area of interest, the FOV may extend beyond the implant site to include the maxillary sinus or opposing dental arch. CT may be considered when CBCT is unavailable; however, dose-sparing protocols must be used.

The use of CBCT before bone grafting helps define both the donor and recipient sites, allows for improved planning for surgical procedures, and reduces patient morbidities. CBCT is best for the evaluation of volumetric and topographic changes of the restored residual alveolar ridge.

**Recommendation 6.** CBCT should be considered when clinical conditions indicate a need for augmentation procedures or site development before placement of dental implants: (1) sinus augmentation, (2) block or particulate bone grafting, (3) ramus or symphysis grafting, (4) assessment of impacted teeth in the field of interest, and (5) evaluation of prior traumatic injury.

**Recommendation 7.** CBCT imaging should be considered if bone reconstruction and augmentation procedures (e.g., ridge preservation or bone grafting) have been performed to treat bone volume deficiencies before implant placement.

### 3. Postoperative imaging

The purpose of postoperative imaging after dental-implant placement is to confirm the location of the fixture at implant insertion. From 3 to 5 years and beyond, imaging is used to assess the bone-implant interface and marginal peri-implant bone height. Titanium implant fixtures inherently produce artifacts such as beam-hardening and streak artifacts obscuring subtle changes in marginal and peri-implant bone. In addition, the resolution of CBCT images for the detection of these findings is inferior to intraoral radiography.

**Recommendation 8.** In the absence of clinical signs or symptoms, use intraoral periapical radiography for the postoperative assessment of implants. Panoramic radiographs may be indicated for more extensive implant therapy cases.

**Recommendation 9.** Use cross-sectional imaging (particularly CBCT) immediately postoperatively only if the patient presents with implant mobility or altered sensation, especially if the fixture is in the posterior mandible.

**Recommendation 10.** Do not use CBCT imaging for periodic review of clinically asymptomatic implants.

Finally, implant failure, owing to either biological or mechanical causes, requires a complete assessment to characterize the existing defect, plan for surgical removal and corrective procedures, such as ridge preservation or bone augmentation, and identify the effect of surgery or the defect on adjacent structures.

**Recommendation 11.** Cross-sectional imaging, optimally CBCT, should be considered if implant retrieval is anticipated.

### CONCLUSIONS

Initial imaging assessment is best achieved with panoramic radiography and may be supplemented with periapical radiography. For the preoperative diagnostic phase, the AAOMR reaffirms that cross-sectional imaging be used for implant site assessment. Furthermore, the AAOMR recommends CBCT imaging as the current method of choice for cross-sectional imaging in that it provides the greatest diagnostic yield at an acceptable radiation dose risk. The decision to perform a CBCT examination must be clinically justified and based on professional judgment (that is, the judgment of the clinician is that the use of CBCT will potentially provide information needed for prosthetic treatment planning, implant selection, and/or surgical placement). The CBCT imaging protocol should include the smallest FOV necessary and available and optimize exposure parameters. For periodic, postoperative implant monitoring, periapical and, in some cases, panoramic images provide adequate imaging. Finally, all CBCT volumes, regardless of clinical application, should be systematically evaluated for signs of abnormalities. This can be performed by the referring dentist or specialist (such as an oral and maxillofacial radiologist) competent in the interpretation of CBCT.
